# Local scalar activity adds to a global vector

One actual narrow-grid experiment: Holmes C=30 · initial physical $d_0$=14 · stationary cue T=300

$$M_0 = \sum_j u_j \Delta s, \qquad M_1 = \sum_j u_j \Delta s\, \mathbf{n}_j, \qquad P = M_1 / M_1(0)$$

Complex numbers package two real Cartesian components. Initial normalization sets P(0)=1.

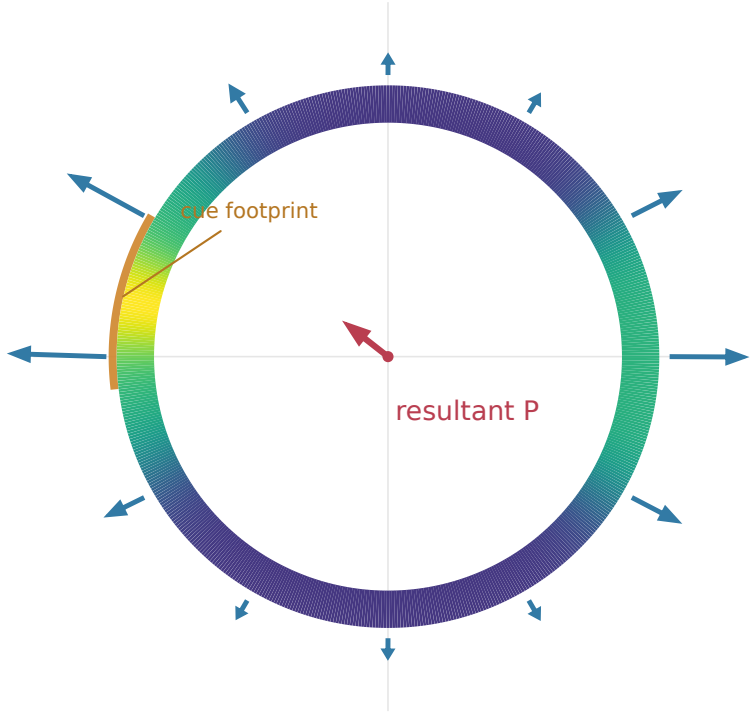

**Initial native basal**

Active amount $M_0/M_0(0)$ = 1.0000

Vector magnitude R = 1.0000

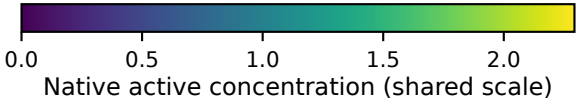

**At cue withdrawal: two active regions**

Active amount $M_0/M_0(0)$ = 1.0290

Vector magnitude R = 0.2589

Blue arrows: exact normalized sums
in twelve 30° sectors. All arrows share one scale.

A smaller resultant can accompany strong local activity.
This is an activity descriptor, without a movement law.

Cue-on states only; the later finite field tail fails and is not used as stability evidence. No site ancestry or intrinsic remodeling-speed claim.
